INTRODUCTION

The St. Lucie Estuary was sampled during June, 2003. One aspect of this evaluation was benthic community characterization, which was accomplished via sample collection by National Oceanic and Atmospheric Administration (NOAA) personnel and laboratory and data analysis by Barry A. Vittor & Associates, Inc. (BVA). Location data for the St. Lucie Estuary stations are given in Table 1 and Figure 1.

METHODS

Sample Collection And Handling

A Young-modified Van Veen grab (area = 0.04 m²) was used to collect three replicate bottom samples at each of the six stations during June, 2003. Macroinfaunal samples were sieved through a 0.5-mm mesh screen and preserved with 10% formalin on ship. Macroinfaunal samples were transported to the BVA laboratory in Mobile, Alabama.

Sediment Analysis

Sediment texture was determined at half-phi intervals using the hydrometer technique for fractions smaller than 44 μm and nested sieves for larger particle fractions. Texture parameters that were computed included percent gravel, sand, and silt /clay. Total organic carbon (TOC) content was measured as ash-free dry weight expressed as a percentage.

Macroinfaunal Sample Analysis

In the laboratory of BVA, benthic samples were inventoried, rinsed gently through a 0.5 mm mesh sieve to remove preservatives and sediment, stained with Rose Bengal, and stored in 70% isopropanol solution until processing. Sample material (sediment, detritus, organisms) was placed in white enamel trays for sorting under Wild M-5A dissecting microscopes. All macroinvertebrates were carefully removed with forceps and placed in labeled glass vials containing 70% isopropanol. Each vial represented a major taxonomic group (e.g. Polychaeta, Mollusca, Arthropoda). All sorted

macroinvertebrates were identified to the lowest practical identification level (LPIL), which in most cases was to species level unless the specimen was a juvenile, damaged, or otherwise unidentifiable. The number of individuals of each taxon, excluding fragments, was recorded. A voucher collection was prepared, composed of representative individuals of each species not previously encountered in samples from the St. Lucie region.

DATA ANALYSIS

All data generated as a result of laboratory analysis of macroinfauna samples were first coded on data sheets. Enumeration data were entered for each species according to station and replicate. These data were reduced to a data summary report for each station, which included a taxonomic species list and benthic community parameters information. Archive data files of species identification and enumeration were prepared.

The Quality Assurance and Quality Control reports for the St. Lucie samples are given in the Appendix.

Assemblage Structure

Several numerical indices were chosen for analysis and interpretation of the macroinfaunal data. Infaunal abundance is reported as the total number of individuals per station and the total number of individuals per square meter (= density). Taxa richness is reported as the mean number of taxa represented in a given station collection.

Taxa diversity, which is often related to the ecological stability and environmental "quality" of the benthos, was estimated using Shannon's Index (Pielou, 1966), according to the following formula:

$$H' = - \sum_{i=1}^S p_i (\ln p_i)$$

where, S = the number of taxa in the sample,
i = the i'th taxa in the sample, and

p_i = the number of individuals of the i 'th taxa divided by the total number of individuals in the sample.

Taxa diversity was calculated using \ln ; however, diversity may also be calculated using \log_2 . Both methods of calculating diversity are common in the scientific literature. The taxa diversity calculated in this report using \ln , can be converted to \log_2 diversity by multiplying the \ln taxa diversity by 1.4427.

Taxa diversity within a given community is dependent upon the number of taxa present (taxa richness) and the distribution of all individuals among those taxa (equitability or evenness). In order to quantify and compare the equitability in the fauna to the taxa diversity for a given area, Pielou's Index J' (Pielou, 1966) was calculated as $J' = H' / \ln S$, where $\ln S = H'_{\max}$, or the maximum possible diversity, when all taxa are represented by the same number of individuals; thus, $J' = H' / H'_{\max}$.

HABITAT CHARACTERISTICS

Water quality and sediment data for the six St. Lucie stations are given in Table 1 and Figure 2. Salinities varied from 0.8 ppt at Station 7 to 8.0 at Station 17. Sediments at the six stations were dominated by the silt+clay fraction (Table 1; Figure 2). The total organic carbon (TOC) fraction of the sediment was greater than 6% at all stations (Table 1, Figure 3).

BENTHIC COMMUNITY CHARACTERIZATION

Microsoft TMExcel spreadsheets are being provided separately to NOAA which include: raw data on taxa abundance and density by replicate, a complete taxonomic listing with station abundance and occurrence, a major taxa table with overall taxa

abundance, and an assemblage parameter table including data on mean number of taxa, mean density, taxa diversity and taxa evenness by station.

A total of 1886 organisms, representing 40 taxa, were identified from the six St. Lucie stations (Table 2). Polychaetes were the most numerous organisms present representing 30.9% of the total assemblage, followed in abundance by bivalves (29.1%), gastropods (25.3%), and malacostracans (11.7%). Polychaetes represented 27.5% of the total number of taxa followed by malacostracans (22.5%), and gastropods (22.5%) (Table 2).

The abundance of major taxa by station are given in Table 3 and Figure 3. The number of taxa per station ranged from 10 at Station 15 to 20 at Station 5. The number of organisms per station ranged from 128 at Station 15 to 461 at Station 5. Annelids (polychaetes) dominated the assemblage at Stations 15 and 17, mollusks dominated at Stations 5 and 12, a mixed assemblage of annelids and mollusks dominated at Station 7, and a mixed assemblage of annelids, mollusks, and arthropods dominated at Station 3 (Figure 3).

The dominant taxon collected from the St. Lucie stations was the bivalve, *Mulinia lateralis* representing 27.6% of the total individuals (Table 4). Other dominant taxa included the polychaete, *Streblospio benedicti*, the gastropod, *Pyrgophorus platyrachis*, and the malacostracan, *Grandidierella bonnieroides* representing 19.6%, 11.9%, and 11.2% of the total individuals collected, respectively (Table 4). The polychaete, *Streblospio benedicti* was the most widely distributed taxon being found at 100% of the stations (Table 4). The distribution of dominant taxa representing > 10% of the total assemblage at each station is given in Table 5.

Mean station taxa richness and station density data are given in Table 6 and Figure 4. Taxa richness varied and ranged from 6.0 (± 2.0) at Station 15 to 12.0 (± 1.7) at Station 5 (Table 6; Figure 4). Station mean densities ranged from 1066.7 organisms/m² (± 425.2) at Station 15 to 3841.7 organisms/m² (± 1040.8) at Station 5 (Table 6, Figure 4). Taxa diversity and evenness are given in Table 6 and Figure 5. Taxa diversity (H') was uniformly low and ranged from 0.91 at Station 5 to 1.60 at Station 7 (Table 6, Figure 5). Taxa evenness (J') ranged from 0.30 at Station 5 to 0.60 at Station 17 (Table 6, Figure 5).
